

**METHOD FOR GENERATING A BASE BAND SIGNAL REPRESENTATIVE
OF THE TRANSMITTED RADIOFREQUENCY POWER, CORRESPONDING
DEVICE AND TRANSMITTING STATION**

5 This invention relates to a method for generating
a base band signal representative of the power
transmitted by a transmitting station. The main
application of the invention is in the field of mobile
radio telecommunication systems.

10 A mobile radio system is currently being
standardized by the 3GPP (3rd Generation Partnership
Project) committee. The CDMA (Code Division Multiple
Access) technology used for this system consists of
modulating each symbol as follows:

- the symbol is modulated by a spreading code
during a spectrum spreading phase, in order to form a
pulse stream, each pulse conventionally being denoted
by the term "chip";
- 15 - each chip then passes through a forming filter,
and is then modulated by a radiofrequency carrier
during a radio modulation phase; each symbol is
emitted with an energy E_s which is the product of the
energy E_c of each chip within this symbol and a
20 spreading factor, this spreading factor denoting the
number of pulses per symbol.

25 A mobile station operating according to the CDMA
technology is shown diagrammatically in figure 1. It
comprises an information source 100 producing symbols
to be transmitted, a spectrum spreading device 102, a
radio modulation device 104 and an antenna 106.

30 In the remainder of the description of the state
of the art, it is assumed that data transmitting
stations are mobile stations of mobile radio systems
and that data receiving stations in this same system
are the base stations. Furthermore, it is assumed that
several mobile stations transmit simultaneously to at

09750762 0102001

least one base station. Using the CDMA technology, several mobile stations can transmit simultaneously on the same carrier frequency. Reception is then possible in the base station if the signals from the mobile stations are received with approximately equal values of the E_s/I ratio, where I denotes the level of interference generated by mobile stations other than the mobile station then considered in communication. A measurement of this ratio defined in the 3GPP committee specifications is denoted SIR (Signal to Interference Ratio) in the rest of this description. Therefore, signals from mobile stations should be received with approximately constant SIR ratios equal to each other. In reality, signals from two mobile stations that do not provide the same services (telephony, data transport, etc.) do not need to be received with equal SIR ratios. This is why the base station has a target SIR ratio denoted SIR_{target} for each mobile station. This ratio SIR_{target} is identical for mobile stations supplying the same services. Therefore, each mobile station should be received by the base station with an SIR approximately equal to SIR_{target} which is associated with the mobile station concerned.

In order to achieve this, the transmission of symbols is divided into time slots. Each time slot contains pilot symbols in addition to the data symbols. For each time slot, the base station estimates the SIR ratio in reception particularly using the pilot symbols, and transmits a TPC (Transmit Power Control) command to the mobile station. The TPC command is received and demodulated by the mobile station before the next time slot. The mobile station increases or reduces its transmission power as a function of the value of this command by means of a feedback loop. This power is usually expressed in decibels.

In order for mobile stations to better control their transmission power, the range of their transmission power must be very large, for example of the order of 80 dB, and they must be able to correct it with a relatively fine resolution, for example of the order of 1 dB. If signals from all mobile stations are to be received with SIR ratios approximately equal to the corresponding SIR_{target} ratios, the mobile station should transmit with a power proportional to the distance separating the transmitting station from the receiving station in order to precisely compensate for the attenuation due to the route. In systems that do not use the CDMA technology, for example in a GSM network, a mobile station close to the base station can transmit "too strongly" without disturbing reception of signals from other mobile stations. This is not possible in CDMA since this mobile station would prevent reception of other mobile stations using the same radiofrequency carrier frequency.

Therefore, before producing symbols representing the transmission power from a mobile station, the mobile station must determine its transmission power. There are several known methods of doing this. Each known method is applied to a radiofrequency signal S' corresponding to a part of the radiofrequency signal S output from the radio modulator 104. For example, the radiofrequency signal S' is output from a passive coupler connected to the output of the radio modulator.

A first method consists of processing the radiofrequency signal output from the passive coupler with an envelope detection device. This envelope detection device is formed by putting a biased diode and a low pass filter in cascade. The major disadvantage of this method is that the signal produced is only representative of the transmitted power for a radio modulation with a constant envelope. Therefore,

it is not applicable to the 3GPP committee system which uses a radio modulation with a non-constant envelope. Furthermore, it cannot be used to process a very high power range. For very low transmission powers, the electrical current corresponding to the coupled radiofrequency signal is negligible compared with the bias current passing through the diode bias resistance. It is then impossible to differentiate the current rectified by the diode from its bias current.

10 A second method consists of demodulating the radiofrequency signal S' by a radio demodulation system performing the inverse function to the radio modulation system. However, the addition of this type of radio demodulation system has a number of disadvantages, particularly in terms of cost, size and energy consumption.

15 A third method consists of processing the radiofrequency signal S' by a logarithmic amplifier that can operate at high frequency. However, the use of this type of logarithmic amplifier is complex and therefore expensive.

20 Therefore, a purpose of the invention is to propose a method and a device capable of generating a base band signal representative of the power of a radiofrequency signal emitted by a transmitting station, this base band signal being useable to control the transmission power from the transmitting station over a wide dynamic range, while maintaining a fine resolution.

30 Thus, a subject of the invention is a method for generating a base band signal representative of the transmission power of a radiofrequency signal transmitted by a transmitting station, characterized in that it comprises the following steps:

35 - extract a part of said radiofrequency signal transmitted by said transmitting station;

09750762.010201

- mix said part of the radiofrequency signal with itself to generate a voltage signal with at least a DC component;
 - filter said voltage signal so as to keep only the DC component of said voltage signal, and
 - amplify said filtered voltage signal using a logarithmic function,
- to generate said base band signal representative of the transmission power of said radiofrequency signal transmitted by said transmitting station.

According to a first embodiment, the voltage signal filtering step is carried out using a low pass filter and the amplification step using a logarithmic function is carried out by a logarithmic amplifier.

- According to a second embodiment, the voltage signal filtering step and the amplification step using a logarithmic function are carried out by the same logarithmic amplifier.

Preferably, the method is implemented in a transmitting station within a telecommunication system using a CDMA type multiple access technology.

Another subject of the invention is a device for generating a base band signal representative of the transmission power of a radiofrequency signal transmitted by a transmitting station, characterized in that it comprises:

- a passive coupler to extract a part of the radiofrequency signal transmitted by said transmitting station;
 - a mixer to mix said part of the radiofrequency signal transmitted by the transmitting station with itself to generate a voltage signal with at least a DC component; and
 - a logarithmic amplifier,
- to generate, from said voltage signal, said base band signal representative of the transmission power of the

09750762.010201

radiofrequency signal transmitted by the transmitting station.

Advantageously, the device further comprises a low pass filter located between said mixer and said logarithmic amplifier to only allow the DC component of the voltage signal output from the mixer to pass.

Another subject of the invention is a transmitting station comprising a device like that described above and a telecommunication system comprising at least one such transmitting station, the telecommunication system being implemented within at least one telecommunication network belonging to the group comprising:

- GSM (Global System for Mobiles) telecommunication networks;
- PCS (Personal Communication System) telecommunication networks;
- UMTS (Universal Mobile Telecommunication System) telecommunication networks.

The characteristics and advantages of the invention will become clearer after reading the following description with reference to the attached drawings, among which :

- figure 1, already described, represents a block diagram of a known transmitting station ;
- figure 2 represents a device implementing the inventive method ; and
- figure 3 represents a variant embodiment of the device in figure 2.

Figure 2 shows a diagram of a device used to implement the method according to the invention. This device is placed in the transmitting station of figure 1. It is also considered that this station emits a radiofrequency signal S with power P.

The device according to the invention comprises firstly a passive coupler 200 that extracts a

09750762-010201

radiofrequency signal S' with power $\alpha.P$ from the radiofrequency signal S . The radiofrequency signal S' is input to a module 202. This module comprises a mixer 204 which is used to mix the radiofrequency signal S' with itself. In the mobile radio system proposed by the 3GPP committee, the radiofrequency signal S (or S') occupies a 5 MHz band around a carrier frequency F_c between 1.920 and 1.980 GHz.

A radiofrequency signal S'' is output from mixer 204, according to the following relation:

$$S''(t) = \beta.S'(t).S'(t)$$

where β represents the conversion gain of mixer 204. Since the signal S' is real, we have $S'(t) = S'^*(t)$ and therefore when β is equal to 1:

$$S''(t) = |S'(t)|^2$$

Therefore the signal S'' is representative of the instantaneous power of the signal S' and therefore of the signal S . More particularly, the DC component of the signal S'' is representative of the power of the radiofrequency signal S' . This DC component is extracted using a low pass filter 206. For the mobile radio system proposed by the 3GPP committee, the cutoff frequency at 3 dB from the low pass filter is typically of the order of 2 kHz. Note that the duration of a time slot is then approximately equal to 666.7 μ s (that is a frequency of 1.5 kHz for the time slots). Therefore, in order to obtain an estimate of the power transmitted during each time slot, a low pass filter with a cutoff frequency of the same order as the frequency of the time slots should be used.

The voltage signal output from the low pass filter 206, representing the transmission power of the radiofrequency signal S expressed in Watts, or on a multiple scale for example in mW, is then applied to

09750762 "010201

the input of a logarithmic amplifier 208. One of the main functions of this logarithmic amplifier is to produce a magnitude V_p representative of the transmitted power expressed on a logarithmic scale, for example in dBm, and no longer in mW, as can be seen on the output signal from the low pass filter 206. This logarithmic amplifier has the advantage that it has a wide dynamic input power range, for example of the order of 80 dB.

Note that the logarithmic amplifier 208 used in the device according to the invention is much less complex than the logarithmic amplifier presented in solutions known in prior art. The device acts on an input signal in the base band and with a small bandwidth, for example of the order of 1 kHz. In other words, the logarithmic amplifier 208 operates at least at low frequencies. The signal obtained at the output from the logarithmic amplifier 208 is representative of the transmitted power expressed for example in dBm, in other words the logarithm of the transmitted power expressed in mW. Thus, the signal obtained is input for example to a feedback loop controlling the transmission power of the transmitting station.

This type of device has the particular advantage that it can supply a base band signal capable of varying approximately linearly as a function of the transmission power of the transmitted radiofrequency signal S.

This type of device may be used in any type of transmitting station, and particularly in a base station and/or a mobile station of a mobile radio telecommunication system.

In particular, the mobile radio telecommunication system may be used in one or more GSM, PCS and/or UMTS type telecommunication networks.

09750762-010201

As shown in figure 3, a variant embodiment could include a logarithmic amplifier 208 with a sufficiently low cut off frequency, within a module 302. This type of logarithmic amplifier 208 with a sufficiently low cutoff frequency would then make it possible to eliminate the low pass filter 206 in module 202 (see figure 2).
